Abstract

During the second half of the twentieth century, the Antarctic Peninsula was subjected to a rapid increase in air temperatures. This was accompanied by a reduction in sea ice extent, increased precipitation and a dramatic retreat of glaciers associated with an increase in heat flux from deep ocean water masses. Isotopic tracers have been used previously to investigate the relative importance of the different freshwater sources to the adjacent Bellingshausen Sea (BS), but the data coverage is strongly biased toward summer. Here we use a regional model to investigate the ocean's response to the observed changes in its different freshwater inputs (sea ice melt/freeze, precipitation, evaporation, iceberg/glacier melt, and ice shelf melt). The model successfully recreates BS water masses and performs well against available freshwater data. By tracing the sources and pathways of the individual components of the freshwater budget, we find that sea ice dominates seasonal changes in the total freshwater content and flux, but all sources make a comparable contribution to the annual-mean. Interannual variability is dominated by sea ice and precipitation. Decadal trends in the salinity and stratification of the ocean are investigated, and a 20-year surface freshening from 1992-2011

is found to be predominantly driven by decreasing autumn sea ice growth. These findings will help to elucidate the role of freshwater in driving circulation and water column structure changes in this climatically-sensitive region.

Keywords: Bellingshausen Sea, Antarctica, Freshwater, Tracers, Sea ice trends

1. Introduction

From the 1950s until the late 1990s the Antarctic Peninsula (AP) warmed more rapidly than any other region in the Southern Hemisphere, with air temperatures increasing by nearly 3°C, though recent changes in wind patterns may have led to a pause of the warming (Turner et al., 2016). Over the same period, the summer surface ocean in the adjacent Bellingshausen Sea (BS) warmed and salinified (Meredith and King, 2005). Unlike elsewhere in Antarctica, the Bellingshausen and Amundsen seas have seen an overall decrease in sea ice duration (Stammerjohn et al., 2012) and extent (Parkinson and Cavalieri, 2012) over the satellite era, with changes focussed on the summer (Holland, 2014). Furthermore, along the AP, 87% of glaciers have retreated since records began (Cook et al., 2005), with mass loss (Wouters et al., 2015) and thinning (Paolo et al., 2015) observed in the southern BS ice shelves. While atmospheric circulation changes and warming are thought to be drivers, they cannot fully explain the ice loss, and recent indications are that the ocean is playing an important role (Wouters et al., 2015; Cook et al., 2016).

The BS can be characterised as being comprised of three water masses.

19 Below the permanent pycnocline, which is around 150-200 m on the shelf,
20 intrusions of Circumpolar Deep Water (CDW) from the Antarctic Circum-
21 polar Current (ACC) onto the shelf provide a source of heat and salt, with
22 the onshelf flow being especially effective within glacially-scoured canyons
23 that cross the shelf (e.g. Zhang et al. (2016), Klinck et al. (2004), Graham
24 et al. (2016)). In the northern BS the CDW layer has thickened and warmed
25 in recent decades (Martinson et al., 2008). This deep layer is overlain by
26 cool, fresh Antarctic Surface Water (AASW), which forms a homogeneous
27 layer around 50-150 m thick in winter, but which is capped in summer by a
28 relatively thin layer that is warmed by insolation and freshened by diverse
29 freshwater inputs. The subsurface temperature minimum that is created re-
30 flects the previous winter's mixed layer, and hence is termed Winter Water
31 (WW) (Klinck et al., 2004).

32 The freshwater balance of the BS is important because salinity controls
33 density in polar waters as thermal effects on density are small (e.g. Tal-
34 ley (2011), chapter 3), and therefore strongly affects ocean circulation and
35 mixing. It has been argued that cyclonic circulation on the shelf is ampli-
36 fied by freshwater-induced buoyancy effects (Savidge and Amft, 2009), and a
37 summer coastal current on the BS shelf is driven at least partially by glacial
38 melt and precipitation (Moffat et al., 2008). Sea ice melting and freezing,
39 and freshwater from meteoric sources (precipitation and evaporation, and
40 the melting of ice shelves, icebergs, and glacier fronts) may all contribute
41 significantly to the mean freshwater balance of the BS and its seasonality.

42 Increases in both precipitation days (Turner et al., 2005b) and snowfall
43 accumulation over longer timescales (Thomas et al., 2008) to the Antarctic

44 Peninsula suggest an increase in precipitation freshwater, particularly since
45 1950. This, along with the extensive retreat of glaciers in recent decades are
46 concurrent with increased calving ice and surface freshwater input into the
47 ocean. The potential consequences range from seasonal effects altering ocean
48 currents and stratification in summer, to influencing the formation of sea ice
49 in winter via surface ocean temperature changes and snow flooding. Sea ice
50 production may be enhanced by an increase in stratification that reduces
51 the oceanic heat flux from below (Hellmer, 2004). There are also important
52 biological consequences, as more glacial meltwater can enhance water column
53 stability and nutrient provision, favouring phytoplankton blooms (Dierssen
54 et al., 2002).

55 Basal melting of ice shelves varies significantly due to changes in the CDW
56 layer and wind strength (Holland et al., 2010; Dinniman et al., 2012), but
57 appears to have increased overall in the BS region (Paolo et al., 2015; Wouters
58 et al., 2015), causing ice-shelf thinning and increased meltwater input into the
59 ocean. This can cause numerous feedbacks, including stabilisation (Hellmer,
60 2004) or destabilisation (Merino et al., 2016) of the water column depending
61 upon the depth of meltwater injection, and intensification of coastal currents
62 (Nakayama et al., 2014).

63 The reduction in BS sea ice extent and duration, with an increased spring
64 meltwater flux (Holland, 2014), has a variety of effects. Reduced summer sea
65 ice cover can increase autumn ice production rates by exposing a greater area
66 of surface water to the atmosphere (Meredith et al., 2010). It can also change
67 basal melt rates of ice shelves (Holland et al., 2010) by altering stratification
68 and therefore the vertical flux of heat from CDW through the water column.

69 Given the strong climatic changes in the BS region in recent years, there is
70 a need to better understand the functional response of the different freshwa-
71 ter components to changing forcings so that their individual and collective
72 impacts on circulation, climate and the ecosystem can be determined and
73 better predicted.

74 There are a number of observations available to assist in closing the fresh-
75 water budget, though whilst spatial and temporal coverage is more complete
76 here than in any other region of the Southern Ocean, it is still strongly bi-
77 ased toward the summer season. In combination with salinity measurements,
78 oxygen isotope ($\delta^{18}\text{O}$) measurements can separate meteoric freshwater inputs
79 from sea ice melt (Meredith et al., 2008), though further deducing contribu-
80 tions from each meteoric sink and source is not possible by this method.
81 Measurements in the northern BS show a general dominance of meteoric
82 water in coastal areas, though years of weak precipitation and/or extreme
83 sea ice can show comparable quantities of sea ice melt (Meredith et al.,
84 2016). Over time there has been a decline in meteoric water in the surface
85 waters adjacent to Adelaide Island, north of Marguerite Bay, due to deep-
86 ening winter mixed layers (Meredith et al., 2013). This is despite increased
87 glacial discharge (Pritchard and Vaughan, 2007) and snowfall (Thomas et al.,
88 2008) in the BS. However, interannual variability in freshwater inputs from
89 different sources and strong regional structure in their injection locations
90 can complicate the interpretation of data on wider temporal and spatial
91 scales (Meredith et al., 2016), highlighting the importance of understanding
92 the three-dimensional spatial variance of freshwater composition over time.

93 Oxygen isotope measurements can also provide palaeoceanographic infor-

94 mation relating to the freshwater content of the water column at particular
95 locations. At Palmer Deep in the northern peninsula, Pike et al. (2013)
96 attribute lowering of $\delta^{18}\text{O}$ in the early Holocene to increased glacial dis-
97 charge coinciding with warming air and sea surface temperatures and ice
98 sheet retreat and thinning, with increased insolation and La Niña events be-
99 ing stronger contributors to warmer temperatures. The method of combining
100 the measurements with known preferences of different diatom species can also
101 be used to investigate seasonal variations in the context of CDW inflow; for
102 example, Swann et al. (2013) found larger seasonality during deglaciation
103 than present-day, attributed to retreat of ice sheets. However, challenges
104 remain with regard to fully ascribing the meteoric water content changes to
105 glacial melt versus precipitation.

106 Overall, although the freshwater system of the BS is arguably better
107 measured and understood than most other Southern Ocean regions, there
108 is still insufficient knowledge given its climatic, cryospheric and ecological
109 importance. Here we use a regional ocean model to investigate the spatial
110 and temporal variations in freshwater sources - sea ice melt/freeze, precipi-
111 tation/evaporation, iceberg melt, ice shelf melt and glacier melt - and their
112 fate in the BS in recent decades. By using passive tracers in the model, we
113 assess the freshwater balance of the BS by quantifying each freshwater com-
114 ponent and its pathways across the shelf. This provides unique insights into
115 the regional freshwater budget, which may be used to consider the ocean's
116 role in sea ice loss and glacial ice retreat in the region.

117 2. Materials and Methods

118 2.1. Model Overview

119 The Massachusetts Institute of Technology general circulation model (MIT-
120 gcm) is used, generally following the configuration of Holland et al. (2014),
121 with the same sea ice and ice shelf components and horizontal and vertical
122 tracer diffusion schemes. Here the horizontal resolution is set to 0.2° , provid-
123 ing an isotropic grid spacing of 6 km in the south and 13 km in the north of
124 the model domain. The model uses a z-level coordinate system with 50 levels,
125 with a vertical resolution varying from 10 m spacing in the top 100 m to over
126 400 m spacing in the deep ocean, to handle surface freshwater inputs and also
127 ice shelf melting at depth on the shelf. To account for complex topography
128 the model uses partial cells, with a minimum open cell fraction of 0.25. The
129 model domain covers the area from 74.4 - 55° S and 95 - 55° W (Figure 1). This
130 area extends beyond the shelf break and includes the Antarctic Circumpolar
131 Current (ACC), important due to its influence on shelf processes.

132 [Figure 1 about here.]

133 The ocean boundaries are forced with the 1990-1999 monthly climatological
134 ocean temperature, salinity, and velocities and sea ice area, thickness and
135 velocities of Holland et al. (2014). We have deliberately chosen this time
136 period from their model as it is the first 10 years after spin-up, so provides
137 a realistic state. We do not use a timeseries for boundary conditions as we
138 are only studying local trends. Sea ice velocities are not prescribed at the
139 boundary if the model predicts ice exiting the domain, to avoid unphysical
140 ice convergence. The run uses BEDMAP2 bathymetry and ice shelf cavi-
141 ties (Fretwell et al., 2013), with any ice shelf thinner than 10 m removed.

142 The model was run from 1979 to the end of 2014 using the climatology of
143 World Ocean Atlas 2005 as initial conditions, with results presented from
144 1989 onwards to allow for 10 years of model spin-up time. All atmospheric
145 forcing variables are provided from the 0.75° resolution ERA-Interim reanal-
146 yses (Dee et al., 2011) at 6-hourly resolution. There is no tidal forcing in the
147 model.

148 *2.2. Glacial Inputs*

149 The ice-shelf melting parameterisation follows De Rydt et al. (2014) so
150 that the melting is dependent on both thermal and haline driving and veloc-
151 ity. All parameters are taken from Holland and Jenkins (1999), apart from
152 the drag coefficient, $c_d = 0.001$, which we tuned from 0.0015 over successive
153 runs so that the modelled melt rate of George VI Ice Shelf (GVIIS) was
154 consistent with observations (section 3.1).

155 The remaining external freshwater inputs are iceberg melting, glacier-
156 front melting, and freshwater runoff. These inputs are collectively repre-
157 sented by a prescribed surface freshwater flux field. Liquid glacier-surface
158 runoff is negligible (van Wessem et al., 2016), and ocean melting at the front
159 of glaciers is taken to be small compared with the calving and subsequent
160 melt of icebergs. Therefore we refer to these terms collectively as iceberg
161 melt, though a fraction may come from ice front melting. Note also that,
162 in reality, iceberg and ice-front meltwater is released at depth, not at the
163 surface, and that this melting entails a consumption of latent heat; neither
164 effect is included in the model, though they may not be insignificant.

165 There are few data available to guide the choice of the prescribed iceberg
166 melting field. There is modelling and observational evidence to suggest that

the freshwater contribution from iceberg melt is localised, with no strong advection of icebergs into or out of the region (Tournadre et al., 2015; Merino et al., 2016), so we adopt the hypothesis that iceberg melting is concentrated close to the southern coastline and is similar in magnitude to local glacial discharge. We assign a flux of 130 Gt/year, calculated from the sum of glacial discharge of each basin along the northwest side of the peninsula found by van Wessem et al. (2016). We distribute this total flux uniformly along the western peninsula coast, concentrated inshore and decreasing linearly to zero 100 km offshore (Dierssen et al., 2002), and uniformly with time in the absence of other data. Both the peak freshwater flux and distribution compare reasonably well with Merino et al. (2016) along a large portion of the peninsula, with slight overestimations in the north.

The sensitivity of the results to these assumptions was tested by altering the magnitude of the total flux, extending the flux further offshore, and randomly redistributing the field to disrupt the spatial pattern. While the magnitude of the resulting freshwater content is altered, its spatial variability does not change. Interannual variability of fluxes are slightly varied due to the additional surface freshwater, but trends in total freshwater content remain similar. Thus whilst this prescription necessarily involves assumptions concerning the spatial and temporal injection of freshwater to the ocean, in the absence of more fully constrained observational fields it is the best that can be achieved.

2.3. Tracers

To determine the extent and nature of the influence of different sources of freshwater, the MITgcm code was developed so that tracing multiple fresh-

192 water tracers from tagged sources (sea ice, precipitation, evaporation, iceberg
 193 melt, and ice shelf meltwater input) is possible, including ice shelf melting
 194 at depth. The sea ice freshwater source/sink includes the effects of melting,
 195 freezing, and flooding of ice-borne snow. Precipitation and evaporation are
 196 dealt with separately because both have a different origin and sensitivity,
 197 and both are handled differently in the model.

198 The standard code allows a passive tracer to be enhanced or diminished
 199 by the total surface freshwater flux according to

$$200 \quad \frac{\Delta\phi}{\Delta t} = \frac{F(\phi_S - \phi)}{\Delta z} \quad (1)$$

201 where ϕ is the concentration of tracer in the ocean, ϕ_S is the concentration
 202 of tracer in the freshwater, F is the volume flux of freshwater in m/s, defined
 203 positive downwards, and Δz and Δt are the top grid cell thickness and time
 204 step. This expression is valid provided that the freshwater is also added as a
 205 material volume flux to the top grid cell. Tracers are subsequently advected
 206 and diffused in the same way as heat and salt.

207 Assuming a constant flux and source concentration of a single tracer, the
 208 solution to (1) is

$$209 \quad \phi = \phi_S(1 - e^{\frac{-Ft}{\Delta z}}) \quad (2)$$

210 This demonstrates that the tracer concentration cannot exceed ϕ_S if the
 211 surface flux is positive (a source), but can become arbitrarily negative relative
 212 to the initial tracer concentration if the surface flux is a sink. For example,
 213 if sea ice grows more than it melts the water becomes saltier, and a negative
 214 sea ice freshwater tracer concentration is left behind.

215 The MITgcm code adaptation for tagging freshwater sources involves ad-
 216 ditional complexity because fluxes of freshwater from other sources dilute

the tracer of the source in question simply by adding additional volume to the ocean that is devoid of that tracer. For example, the formulation for tracers ϕ_1 and ϕ_2 with source concentrations ϕ_{S_1} and ϕ_{S_2} and fluxes F_1 and F_2 respectively is

$$\frac{\Delta\phi_1}{\Delta t} = \frac{1}{\Delta z}(F_1(\phi_{S_1} - \phi_1) - F_2\phi_1) \quad (3)$$

$$\frac{\Delta\phi_2}{\Delta t} = \frac{1}{\Delta z}(F_2(\phi_{S_2} - \phi_2) - F_1\phi_2) \quad (4)$$

As such, a particular tracer concentration in any given grid cell is affected by the fluxes of all tracers, but only the concentration of the relevant source.

In this study we trace a total of 6 freshwater sources: sea ice melt/freeze, precipitation, evaporation, iceberg melt, ice shelf melt, and a tracer of the total freshwater source. We set the initial concentration of all tracers to be 0, and then allow them to evolve to represent the contribution from freshwater sources, which are set to a tracer value of 1 for each source. A seasonally varying quasi-steady state is obtained when the local tracer sources and sinks are balanced by the lateral fluxes of tracer out of the domain, which occurs within the model spin-up period. All tracers are set to zero on boundary inflows, i.e. we are only tracing locally-sourced freshwater. Further information can be found in Regan (2017).

3. Climatological results

3.1. Model validation

[Figure 2 about here.]

Figure 2 shows the mean climatological bottom potential temperature and salinity for the period 1989-2014 inclusive, along with winter (July-September)

241 sea ice thickness, concentration, and drift. The west Antarctic Peninsula shelf
242 is fresher and warmer than the deep waters of the ACC, reflecting the fact
243 that it has shallower bathymetry. Warmer, saline waters fill bathymetric
244 troughs and canyons, highlighting areas where CDW intrudes onto the shelf
245 from the ACC. Shallow areas immediately adjacent to the coast are colder
246 and fresher, reflecting the depth-variation in the water-column properties.
247 Model resolution is important for allowing CDW onto the shelf (Graham
248 et al., 2016), but while temperatures are slightly lower than core CDW tem-
249 peratures, there is little deviation from the World Ocean Atlas fields that
250 were used to initialise the model, showing that a suitable model climatology
251 is achieved for the purpose of this study.

252 Crucially for this study, comparisons with CTD profiles are able to vali-
253 date the salinity and freshwater content. Figure 3 shows the vertical profiles
254 of salinity and derived sea ice melt and meteoric water content of location
255 $65^{\circ}52.6'$ S, $68^{\circ}10.0'$ W (Figure 1, location P) reproduced from Meredith et al.
256 (2016), along with the associated model output. The general behaviour of
257 each field is captured. Temperature data are much more commonly avail-
258 able, so we compare our model to the World Ocean Atlas. In both the model
259 and observations, most variation in salinity and freshwater content is seen in
260 the top 50 metres of the water column (Figure 3), though the mixed layer
261 signal in temperature is shallower in the model. The model underpredicts
262 meteoric water content in the top 50 metres, and generally over-predicts sea
263 ice meltwater at the surface. At depth there is a net loss of sea ice meltwater
264 in most years which the model is able to recreate successfully, though the in-
265 terannual variability in the model at depth is less than in observations. The

266 model successfully estimates high sea ice melt and fresher waters in 2014,
267 though 2011 and 2012 are less comparable, with observed negative sea ice
268 content not modelled. Overall, the comparison is encouraging considering
269 the difficulties inherent in modelling specific events using reanalysis forcing
270 and relatively coarse model resolution, which are expected to produce less
271 variability.

272 [Figure 3 about here.]

273 The modelled sea ice can be compared with satellite observations of ice
274 concentration and drift (e.g. Holland and Kimura, 2016) and thickness (e.g.
275 Xie et al., 2013). The wintertime ice concentration is in good agreement
276 with observations, though the summer ice cover is too low (section 4.2).
277 Modelled ice drift accurately captures the eastward ice current to the north
278 and westward coastal current (not shown in the north due to vector resolu-
279 tion). Modelled ice thicknesses are realistic, with thicker ice near Wilkins
280 and Abbot ice shelves (locations shown in Figure 1).

281 An assessment of the modelled ice shelf melt flux is an important re-
282 quirement of this study. Table 1 summarises the six main ice shelves in the
283 domain and their melt rates derived from both the model and glaciological
284 mass budgets. Note that Abbot Ice Shelf is only partially covered by the
285 model. George VI Ice Shelf (GVIIS) is the only ice shelf where there are ad-
286 ditional data from oceanographic observations, summarised in Holland et al.
287 (2010). The modelled GVIIS melting (4.74 ± 0.19 m/yr) is within 3-5 m/yr,
288 the range quoted by Jenkins and Jacobs (2008), but slightly higher than the
289 values found by both Rignot et al. (2013) (3.8 ± 0.7 m/yr) and Depoorter
290 et al. (2013) (2.88 ± 0.83 m/yr). Wilkins and Abbot ice shelf melt rates are

291 within error bars of the latter two studies but Bach, Stange and Venable
292 melt rates are all significantly underestimated by the model. Relatively low
293 model resolution and poorly-known ice-shelf cavity geometry are significant
294 limiting factors and therefore we would not expect to be able to fully recre-
295 ate ice shelf melt rates in these smaller, poorly sampled cavities, and as such
296 we do not place much faith in their modelled melting. Future improvements
297 to the model can be made once suitable surveys of the cavities have been
298 conducted. Further model validation is provided in Regan (2017).

299 [Table 1 about here.]

300 3.2. *Freshwater climatology*

301 [Figure 4 about here.]

302 In the long-term mean, each climatological freshwater source into the Belling-
303 shausen Sea is of comparable magnitude (Figure 4, Table 2), albeit with
304 strong spatial variation. In particular, there is a clear difference between the
305 north and south, separated by Alexander Island and GVIIS. In the north,
306 there is a strong positive contribution of freshwater extending across the shelf
307 break out into the ACC, comprising precipitation, sea ice melt, and imposed
308 iceberg melt. Strong sea ice freezing results in a net loss of sea ice freshwater
309 directly adjacent to the entire coastline. This is particularly apparent in the
310 south, where it is only countered by ice shelf melt and imposed iceberg melt;
311 the cooler climate reduces both the precipitation rate and the open ocean
312 area into which it falls.

313 [Figure 5 about here.]

314 The surface tracer concentration fields (Figure 5) reflect the spatial distribu-
315 tion in freshwater fluxes, their relative magnitudes, and redistribution and
316 mixing of the freshwater by ocean processes, and demonstrate that the fresh-
317 water composition in any particular location cannot in general be deduced
318 from fluxes alone (or vice versa). Over the deep ocean, evaporation, pre-
319 cipitation, and sea ice melt dominate the total freshwater budget. On the
320 western AP shelf all components have localised contributions, resulting in
321 total freshwater content exceeding 3% concentration in coastal areas and 5%
322 in Marguerite Bay. Evaporation and precipitation demonstrate the role of
323 westward advection along the coastal current from their source regions in the
324 north.

325 Sea ice meltwater accumulates in the far west despite this being a region
326 of net freezing (Figure 5e). Adjacent to this sea ice meltwater lies a pool
327 of water depleted in sea ice tracer at the surface, due to strong ice growth
328 in polynyas in Eltanin Bay (Holland et al., 2010). This is countered by
329 meteoric freshwater to result in a net positive concentration of freshwater
330 tracer overall, masking the sea ice signal, which reaffirms the need to consider
331 the behaviour of individual freshwater components. All tracer concentrations
332 are elevated east of Ronne Entrance, particularly in Marguerite Bay. Ice
333 shelf melt reaches the surface in large volumes in Marguerite Bay but not
334 elsewhere.

335 [Figure 6 about here.]

336 The surface model layer (top 10 m) accounts for less than 5% of the full
337 water column tracer content and masks significant features at depth. Depth-
338 integrals of the tracers in Figure 6 show that while surface freshwater is

339 concentrated around the north of GVIIS and Alexander Island, the signals
340 from surface inputs summed over all depths gather in Eltanin Bay. This
341 occurs because the model predicts strong ice growth and convection in win-
342 tertime polynyas in this region (Holland et al., 2010), which mix the surface
343 tracers down through the water column. Convection does not reach the sea
344 bed, so the model is consistent with observations of a warm CDW layer in
345 this region (Zhang et al., 2016). However, this deep mixed layer is unverified
346 by observations and could be unrealistically deep.

347 The vertically-integrated tracers show that ice-shelf melting (Figure 6f)
348 is the largest contributor to freshwater over the full water column. At both
349 ends of GVIIS, the vertically integrated ice shelf meltwater shows a strong
350 enhancement, and this water is also able to reach the surface ocean in the
351 north (Figure 5f).

352 The structure can be seen in vertical sections through Ronne Entrance
353 (Figure 7) and Marguerite Trough (Figure 8). In Ronne Entrance, the surface
354 layers are stratified with high levels of freshwater due to the surface inputs,
355 with prescribed iceberg melt highest near the coast and evaporation and
356 precipitation having more influence further across the shelf. A sub-surface
357 layer of brine-enhanced water (Figure 7e) traces the deeper winter water from
358 sea ice formation; the magnitude of this exceeds 0.5% offshore. The sea ice
359 tracer has more influence at depth than the tracers of other surface inputs,
360 though they counter its influence in the total freshwater content. Close to
361 the coast, ice shelf meltwater dominates the intermediate depths down to 400
362 metres, the bulk of which remains at depth below the sea ice signal as its
363 salinity is higher than the surface layers, resulting in a second area of high

364 freshwater concentration.

365 In Marguerite Trough (Figure 8), stratification of meltwater-enriched sur-
366 face layers extends to the shelf break, but high levels of sea ice and ice shelf
367 meltwater dominate at the ice shelf front. Ice shelf meltwater is able to reach
368 the surface due to it being fresher than the meltwater in Ronne Entrance (Fig-
369 ure 7f) and the ambient water. The concentration of sea-ice brine-enhanced
370 water is lower in Marguerite Trough than in Ronne Entrance, and the surface
371 sea ice meltwater is stronger.

372 [Figure 7 about here.]

373 [Figure 8 about here.]

374 The sea ice tracer shows a strong vertical gradient, with a large positive tracer
375 concentration at the surface everywhere except in Eltanin Bay (Figure 5e)
376 and a larger volume of brine-enhanced water at depth (Figure 6e). With
377 the simulations starting from zero sea ice tracer, positive meltwater fluxes
378 are added to the surface in spring, and negative fluxes are extracted over a
379 greater depth in autumn. This gradually forms the vertical structure in the
380 model. We ascribe the overall dominance of negative tracer values (Figure
381 6e) to both the preferential export of surface meltwater out of the domain
382 by the coastal current, and sea ice drift.

383 3.3. *Freshwater seasonality*

384 [Figure 9 about here.]

385 On an annual mean, the magnitude of freshwater fluxes and their associated
386 tracers are comparable. However, the seasonal variation differs markedly

387 between tracers. The salinity at the surface, which receives the majority of
388 freshwater inputs, has a strong seasonal cycle (Figure 9). The freshest waters
389 occur in the summer and near to the coast, extending out to the shelf break,
390 and to a lesser extent out to the maximum extent near 64 °S. Spring and
391 autumn have similar salinity distributions, freshest in the north where there
392 are multiple freshwater inputs. In the winter there is a net salinification in
393 Eltanin Bay, which is also seen on a small scale in autumn and remains in
394 spring.

395 [Figure 10 about here.]

396 The seasonal distribution of salinity (Figure 9) largely mirrors the distribu-
397 tion of the sea ice tracer (Figure 10). The autumn and spring sea ice tracers
398 highlight the dominance of freezing in Eltanin Bay, and a large amount of
399 melt remains close to Alexander Island late into autumn. High meltwater
400 content in summer is offset by freezing in winter, providing opposing sig-
401 nals that partly compensate on an annual mean, dependent on the effect of
402 the mixed layer depth. However, while sea ice tracer content has the most
403 extreme magnitude in summer and winter (Figure 10), the sea ice freshwa-
404 ter flux is maximised in spring and autumn (Figure 11). Precipitation also
405 shows seasonal variation in the form of a larger freshwater input in autumn
406 than spring that extends further south to Marguerite Bay, especially close
407 to the peninsula. This is not cancelled by evaporation (not shown). Glacial
408 freshwater sources (ice shelf melt and prescribed iceberg melt) are seasonally
409 uniform; the dominant ice shelf meltwater contribution from GVIIS displays
410 little variability, and no data is available to suggest a seasonal cycle of iceberg
411 melt in the BS is significant.

412 [Figure 11 about here.]

413 [Figure 12 about here.]

414 The seasonality of the spatially variable fluxes and tracers results in a
415 strong seasonal cycle of salinity at different depths on the shelf (Figure 12).
416 In winter, the upper ocean has relatively uniform salinity due to the deepened
417 mixed layer (Figure 12a). The onset of surface freshening occurs in October,
418 with the minimum salinity occurring in January. At deeper levels the lowest
419 salinities occur later in summer following the onset of the deepening mixed
420 layer, and are less pronounced.

421 The annual average, seasonal variability, and interannual variability of
422 each component are quantified in Table 2.

423 [Table 2 about here.]

424 The seasonal cycle in the sea ice flux is an order of magnitude larger than
425 seasonal variation in other freshwater inputs (Figure 12b, Table 2). Precip-
426 itation and evaporation peak in summer, once sea ice has melted. While
427 their seasonal variability is higher than glacial inputs, their annual mean
428 contribution is comparable.

429 The domination of sea ice variability on the seasonal flux cycle (Figure
430 12b) is reflected in the seasonality of its associated tracer concentration (Fig-
431 ure 12c). But while instantaneous freshwater fluxes are dominated by sea ice,
432 the annual-mean flux, and hence the total freshwater concentration, is a bal-
433 ance of all sources. Table 2 shows that precipitation is the biggest annual
434 contributor, followed by ice shelf meltwater flux, with sea ice contributing the
435 least, negative due to seasonal refreezing. The associated precipitation and

ice shelf tracers are similarly large, with ice shelf melt dominating as shown earlier. The sea ice tracer content has a negative sign due to net freezing that overrides the strong positive signal from surface meltwater, indicating a high residence time of the subsurface brine-enhanced saline waters gained through seasonality of the mixed layer depth. The seasonal variability in freshwater tracers is lagged from the variability in its sources, with the peak sea ice and total freshwater tracer in February-March and peak precipitation tracer in June.

4. Interannual variability and trends

4.1. Variability

To investigate the temporal variability of freshwater on the shelf, the mean seasonal cycle has been removed to provide a timeseries of anomalies, shown as annual averages in Figures 12d-12f. Salinity in the top 100 metres shows interannual variability (Figure 12d), while deeper layers show little deviation from the mean.

While the seasonal cycle of sea ice flux is an order of magnitude larger than the other freshwater sources (Figure 12b), the interannual anomaly of both sea ice and precipitation flux are dominant, exceeding ten times and five times that of the least variable (Figure 12e; Table 2). The dominance of these in flux anomalies is apparent to a lesser extent in interannual variability of tracer content, with ice shelf melt and iceberg melt displaying more interannual variability than their associated fluxes (Table 2).

Anomalies in flux lead to changes in tracer content (Figure 12f). High sea ice melt tracer in 1989-1990 dominates the total freshwater tracer. This

460 is followed by a period of low total freshwater tracer due to low precipitation
 461 freshwater content in 1992-1995. From 1995, lower than average sea ice melt
 462 tracer broadly increases until 2006, where it remains higher than average until
 463 2012. From 2006 the precipitation and ice shelf melt help to sustain high total
 464 freshwater content. After 2011 the model freshwater content dramatically
 465 decreases due to a large decrease in sea ice meltwater, despite an increase in
 466 freshwater content from precipitation and iceberg melt. The total freshwater
 467 tracer is mirrored by salinity at the surface (Figure 12d). In general, sea ice is
 468 the strongest contributor to variability in both total freshwater flux and total
 469 tracer, with a correlation of over 0.8 at the 99% significance level (Table 2);
 470 where there is a large difference this is due to precipitation offsetting the sea
 471 ice signal (Figure 12e,f).

472 *4.2. Trends*

473 Linear trends in salinity and freshwater tracers on the BS shelf are shown
 474 in Table 3. Over the full time period (1989-2014) there are no significant
 475 trends in salinity over most of the water column. However, there are com-
 476 pensating trends in the individual freshwater components. The precipita-
 477 tion flux from ERA-Interim in the model increases over time, as in obser-
 478 vations (Thomas et al., 2008), contributing to more precipitation tracer on
 479 the shelf (Figure 12f). Significantly, the iceberg melt tracer increases over
 480 the model period despite having a constant prescribed flux, showing that
 481 ocean dynamics are paramount; the input flux outweighs export from the
 482 shelf during this period. This is probably due to meltwater accumulation
 483 in regions with a long residence time, such as Eltanin Bay (Figure 6), and
 484 could have subsequent effects on the seasonal Antarctic Peninsula Coastal

485 Current (Moffat et al., 2008). Ice shelf meltwater content has an insignifi-
486 cant trend, despite observations suggesting an increase in melting in recent
487 years in the area (Paolo et al., 2015).

488 [Table 3 about here.]

489 The dominant feature in both the surface salinity and freshwater tracers
490 is a surface freshening from 1992-2011 (Figures 12d and 12f) which can be
491 largely attributed to an increase in freshwater tracer from sea ice. Table 3 also
492 shows the linear trends in all components during this shorter time period. It
493 should be noted here that the anomalously low salinity in 2011 does partially
494 drive the 1992-2011 trend. However, apart from surface salinity, trends that
495 occurred in 1992-2011 remain if looking at 1992-2010, albeit to a smaller
496 extent. We now focus on the strong changes occurring during this period
497 because 1) it enables comparison with the many previous studies that have
498 examined these changes, and 2) it provides a case study of strong decadal
499 freshwater change.

500 The tracers associated with precipitation, evaporation, and iceberg melt-
501 ing show significant changes in freshwater from 1989-2014, but their sum does
502 not create significant freshening at the surface. Over 1992-2011, however, the
503 clear freshening can be attributed to significant increases in freshwater trac-
504 ers, of which iceberg melt, evaporation and sea ice melt are significant con-
505 tributors at the 95% level (Table 3). Increases in precipitation and ice shelf
506 melting also contribute to the freshening, albeit significant at only the 90%
507 level. The main difference is sea ice; an increase in sea ice tracer contributes
508 over half the total freshwater trend in 1992-2011, but has no significant trend
509 over the whole model period.

510 Figure 13 shows the seasonal trends in sea ice concentration from obser-
511 vations (Cavalieri et al., 1996) over the full time period 1989-2014, and the
512 identified period of increased melting 1992-2011. A loss of sea ice is observed
513 over both time periods in summer and autumn. In winter and spring, how-
514 ever, 1989-2014 shows an increase in sea ice while 1992-2011 shows a general
515 ice loss. The strong summer-intensified ice loss from the BS (Holland, 2014)
516 is robust for all time periods but during 1989-2014 there is no annual-mean
517 trend because winter ice gain offsets summer ice loss.

518 Figure 14 shows the modelled sea ice concentration, drift, thickness, and
519 freshwater flux trends over the period of increased sea ice freshwater 1992-
520 2011. Comparing the model to observations (Figure 13) shows that overall
521 ice concentration trends are very generally captured, though the model ice
522 loss is not focused on the coastline, and little ice exists in summer. Whilst
523 summer and autumn losses are recreated, the loss in winter and spring is
524 not. In any model forced by coarse reanalysis winds, we can only expect
525 to reproduce the broad features of complex regional changes such as these,
526 which is sufficient for our shelf-wide analysis of freshwater trends.

527 The 1992-2011 freshening can be explained by trends in seasonal ice mo-
528 tion and thickness (Figure 14). In autumn and winter, reduced sea ice extent
529 across the BS is caused by strong northerly wind trends forcing the sea ice
530 towards the BS coast, resulting in ice thinning in the north and thickening at
531 the southern coastline (Holland et al., 2014), as shown in the thickness and
532 velocity vector trends of Figure 14. This wind-driven change is accompanied
533 by a significant reduction in freezing in autumn on the northern BS shelf,
534 and consequently a reduction in autumn and winter ice concentration and

535 thickness. It is this reduction in brine rejection on the shelf that causes the
536 increase in annual-mean sea ice freshwater content (Table 3). This is at odds
537 with Meredith and King (2005) (hereafter MK), who find that observed de-
538 creasing autumn sea ice production results in saltier surface layers. However,
539 MK find significant salinification in the north, which both contains off-shelf
540 waters and does not account for southern changes as in our calculations.
541 Additionally, the time period of observations is different to this study.

542 MK use a simple 1D column model to argue that increased ice produc-
543 tion leads to increased meltwater input in summer and thus a fresher surface
544 layer. Thus their observed trend to higher summer salinity is consistent with
545 reduced ice production. The present paper concludes that a year-round fresh-
546 ening is caused by reduced ice production. The two arguments may at first
547 appear contradictory. However, the sole intention of the MK model was to
548 consider the seasonality in the impact of a given annual-mean ice anomaly.
549 That study compared simulations with two different values of a fixed re-
550 peating cycle in ice production. By contrast, the present study considers
551 interannual trends in the annual-mean ocean salinity, driven by a progres-
552 sively evolving annual-mean ice production. The present study also considers
553 freshwater forcings other than sea ice, and is fully conservative in three di-
554 mensions. Thus the MK model explains the expected seasonality of trends
555 in an idealised setting, while the present study explains the magnitude of
556 annual-mean trends in a more realistic scenario.

557 [Figure 13 about here.]

558 [Figure 14 about here.]

559 5. Conclusions

560 This study uses a numerical model equipped with freshwater tracers to
561 derive a freshwater budget of the Bellingshausen Sea. We find that sea ice
562 dominates the seasonal freshwater cycle such that sea ice fluxes are instanta-
563 neously an order of magnitude larger than any other source. However, on an
564 annual mean, all fluxes (precipitation, evaporation, sea ice, icebergs and ice
565 shelves) are comparable, while sea ice and precipitation dominate interannual
566 variability and trends. The on-shelf content of each tracer largely reflects this
567 also, though the dominance of sea ice tracer in the seasonal cycle is damp-
568 ened. Each component has its own temporal and spatial variability, and none
569 can be neglected a priori. Ice shelf melt is the largest single contributor to
570 mean freshwater content in the BS, thus it is vital that its contribution is
571 further understood in light of recent changes to ice shelf melting. This is par-
572 ticularly key for isotopic analysis, where high meteoric water content in some
573 areas (e.g. Meredith et al., 2013) is not able to be attributed to individual
574 sources.

575 Ice shelf melt is less pronounced in the surface despite being the dominant
576 contributor over the whole water column. South of George VI Ice Shelf, the
577 peak ice shelf meltwater resides at intermediate depths, while to the north
578 it reaches the surface, agreeing well with Jenkins and Jacobs (2008). This
579 result has important implications for the interpretation, and comparison, of
580 geographically-separated sediment core $\delta^{18}\text{O}$ records that may be recording
581 waters from different sources, or missing the bulk of some freshwater com-
582 ponents, despite the $\delta^{18}\text{O}$ being measured on organisms living at the same
583 depth and in the same ecological niche. While it confirms the presence of ice

shelf meltwater in the north away from its source, as inferred from sediment
cores (e.g. Pike et al., 2013), it suggests deeper meltwater content may be
missed.

Seasonal and spatial variation in freshwater fields can be hidden by sparsity of data. In Eltanin Bay, strong winter salinification from sea ice growth is masked by a net positive total freshwater content from meteoric sources, showing the importance of identifying the full regional composition of freshwater. Additionally, when assessing the freshwater balance, the different origins of freshwater content cannot be deduced from fluxes, or vice versa, since many freshwater constituents are far removed in space and time from their sources.

Over the full model period (1989-2014) there are no overall salinity trends despite increasing precipitation, evaporation, and iceberg melt tracers (the latter increasing despite a constant prescribed flux). Ocean observations are insufficient to determine whether any salinity trends occurred in reality during this period, though some components of the freshwater budget clearly changed (e.g. Parkinson and Cavalieri, 2012; Wouters et al., 2015). However, a strong surface freshening occurs during 1992-2011, a period studied by several previous authors (e.g. Parkinson and Cavalieri (2012); Holland and Kwok (2012); Holland et al. (2014)). In our model, a strong decrease in ice growth in autumn causes this freshening, driven by northerly wind trends. This illustrates the importance of sea ice to decadal freshwater change.

One of the main limitations of this study is the use of a spatially and temporally uniform composite runoff field, representing liquid runoff, ice front melting, and iceberg melt. Given the significance of freshwater injec-

tion depth on water column stability, prescribing iceberg melting in surface coastal areas is likely to miss important features in the Bellingshausen Sea freshwater composition. Another significant limitation is that the sparsity of observations of freshwater content in the polar regions means that such models of freshwater processes cannot be fully validated. This is particularly relevant given the reasonably low resolution of the model at the coast which is likely to affect freshwater fields in those areas, particularly precipitation which originates from a coarse dataset that therefore may not fully resolve the effects of the AP mountains. The large spatial and temporal variation of our modelled tracers highlight the need for dedicated $\delta^{18}\text{O}$ observations to complement modelling efforts in order to understand the relative importance of each freshwater source.

6. Acknowledgements

This work was funded through a NERC DTG studentship (Project Reference: NE/L501633/1) to the British Antarctic Survey. This paper is a contribution of the BAS Polar Oceans programme. We thank Melchior van Wessem and colleagues at the Institute for Marine and Atmospheric Research Utrecht for providing data for use in computing the iceberg melt field. The MITgcm model is an open source model (mitgcm.org) and was forced with data as described in the methods section.

792 **List of changes**

793 List of Figures

794	1	Model domain. Coloured is BEDMAP2 bathymetry, with con-	
795		tours shown at 100, 500, and 1000 metres. Ice shelves are	
796		shown in grey, with underlying bathymetry contours shown.	
797		Also provided in red are key locations, where EB = Eltanin	
798		Bay, RE = Ronne Entrance, AI = Alexander Island, MB =	
799		Marguerite Bay and P = Palmer LTER grid point 400.1, used	
800		for validation. Ice shelves on the west Antarctic Peninsula are	
801		shown with black arrows, where A = Abbot, V = Venable, S =	
802		Stange, B = Bach, W = Wilkins and G = George VI. Sections	
803		through Belgica Trough leading to Ronne Entrance (S1) and	
804		Marguerite Trough (S2) are also shown (black). Inset shows	
805		the Bellingshausen Sea and model domain (blue) in relation	
806		to the Southern Ocean and Antarctic Ice Sheet.	39
807	2	Annual mean a) salinity and b) potential temperature at the	
808		seabed for the period 1989-2014. Bathymetry contours shown	
809		in grey at 100, 500, and 1000 metres, with the 1000 metre	
810		isobath shown in black. Mean winter (JAS) sea ice thickness	
811		(c) and extent (d) is shown over the same period masked where	
812		sea ice concentration is below 15%, with ice shelves in grey.	
813		Vectors of ice velocity at 12 grid point intervals are also shown.	
814		Inset highlights the effect of the coastal current on the mean	
815		winter sea ice velocities.	40
816	3	Salinity (a,d), sea ice melt (b,e) and meteoric water content	
817		(c,f) at 65°52.6' S, 68°17.0' W (see Figure 1). Top row (a-c) re-	
818		produced from Meredith et al. (2016) for validation purposes,	
819		with bottom row (d-f) showing the model equivalent for Jan-	
820		uary 2011 (black), 2012 (red), 2013 (green) and 2014 (blue).	
821		Climatological potential temperature at the same location (g)	
822		is shown for the model (black, averaged over 1989-2014, after	
823		the spin-up period) and World Ocean Atlas data (red).	41
824	4	Climatology of freshwater fluxes at injection depth (positive	
825		downwards) for a) total freshwater, b) iceberg melt, c) evap-	
826		oration, d) precipitation, e) sea ice and f) ice shelf melt, all	
827		shown on the same scale. Grey regions indicate ice shelves,	
828		with the shelf break contoured at 1000 metres.	42

829	5	Climatological surface concentration of tracers from 1989-2014	
830		for a) total freshwater, b) iceberg melt, c) evaporation, d)	
831		precipitation, e) sea ice and f) ice shelf melt. Grey regions	
832		indicate ice shelves, with the shelf break contoured at 1000	
833		metres. Note the different colour scale for total freshwater. . .	43
834	6	Climatological water-column integral of each tracer from 1989-	
835		2014, in metres. a) Total freshwater b) iceberg melt, c) evap-	
836		oration, d) precipitation, e) sea ice and f) ice shelf melt all	
837		shown on the same scale. Bathymetry contours are shown at	
838		100, 500, and 1000 metres.	44
839	7	Vertical sections from the shelf break, through the deepest	
840		part of Belgica Trough from north-west to south-east through	
841		Ronne Entrance (S1 in Figure 1) for the climatology of a) total	
842		freshwater content, b) iceberg melt, c) evaporation, d) salinity,	
843		e) precipitation, f) sea ice, g) ice shelf melt, and h) potential	
844		temperature. Contours are shown at 0.5‰ intervals.	45
845	8	Vertical sections from George VI Ice Shelf through the deepest	
846		part of Marguerite Trough to the shelf break (S2 in Figure 1)	
847		for the climatology of a) total freshwater content, b) iceberg	
848		melt, c) evaporation, d) salinity, e) precipitation, f) sea ice,	
849		g) ice shelf melt, and h) potential temperature. Contours are	
850		shown at 0.5‰ intervals.	46
851	9	Average seasonal surface salinity, clockwise from top left: a)	
852		summer, b) autumn, d) winter and c) spring. Grey regions	
853		indicate ice shelves, with the shelf break contoured at 1000	
854		metres.	47
855	10	Seasonal distribution of sea ice tracer at the surface. Seasons	
856		are shown clockwise from top left: a) summer, b) autumn, d)	
857		winter and c) spring. Grey regions indicate ice shelves, with	
858		the shelf break contoured at 1000 metres.	48
859	11	Seasonal distribution of fluxes of (a,d) total freshwater, (b,e)	
860		net sea ice melt/growth, and (c,f) precipitation for the spring	
861		(top) and autumn (bottom). Grey regions indicate ice shelves,	
862		with the shelf break contoured at 1000 metres.	49

863	12	Temporal variation of freshwater on the BS shelf (shallower	
864		than 1000 metres). Plots on the left show (from top) sea-	
865		sonal cycles of a) mean salinity at different depths; b) area-	
866		integrated freshwater fluxes; and c) volume-integrated tracer	
867		content. Plots d)-f) on the right show the timeseries of devia-	
868		tions from the mean seasonal cycle, plotted as annual averages.	
869		Note the second y-axis in panel b) for iceberg melt, evapora-	
870		tion, precipitation and ice shelf melt.	50
871	13	Trends of observed satellite-derived sea ice concentration from Cav-	
872		alieri et al. (1996) for the full modelled period 1989-2014 (top)	
873		and period of increased sea ice flux, 1992-2011 (bottom). Con-	
874		fidence contours are shown at the 90% (black), 95% (grey) and	
875		99% (white) levels. The shelf break is shown in black and ice	
876		shelves are in grey.	51
877	14	Modelled trends in sea ice area (top), thickness and drift (mid-	
878		dle), and sea ice freshwater flux (bottom, positive downward)	
879		from 1992-2011. Confidence interval contours are shown at	
880		the 90% (black), 95% (grey) and 99% (white) levels. The	
881		shelf break is shown in black and ice shelves are in grey.	52

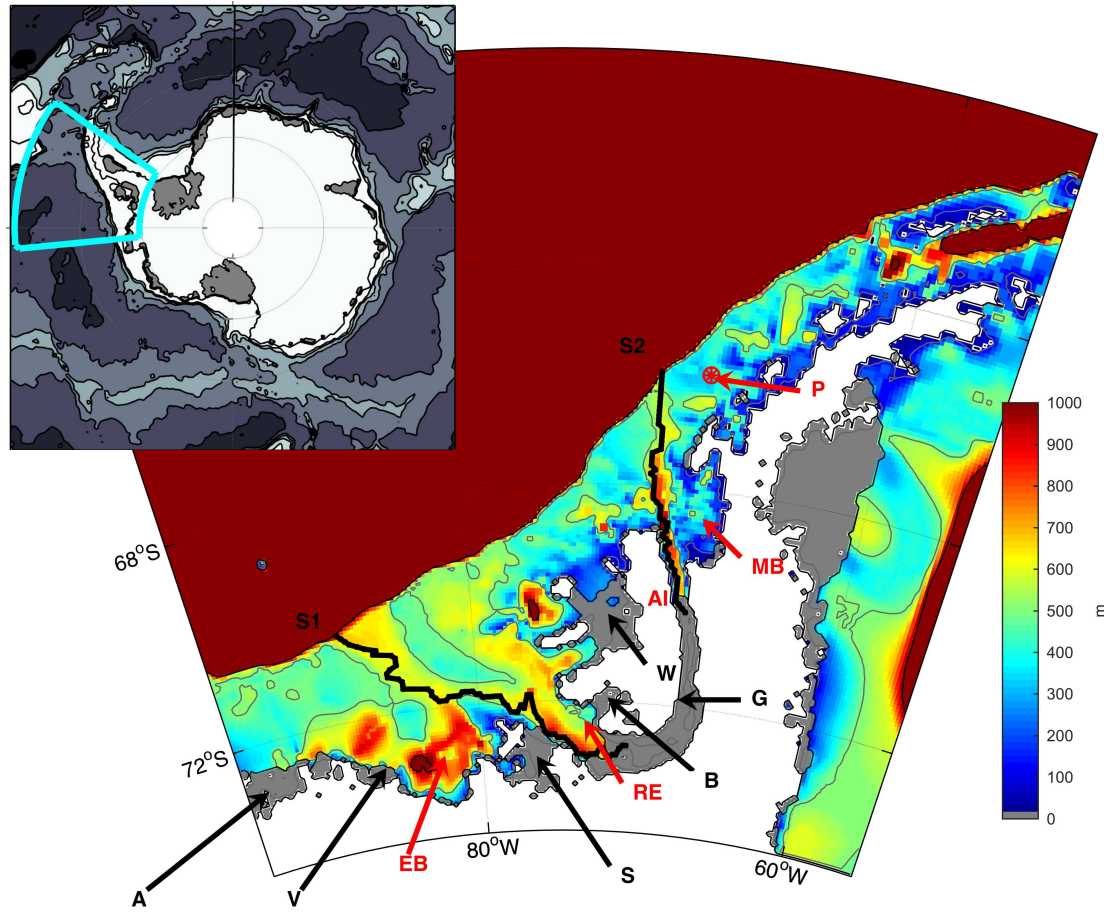

Figure 1: Model domain. Coloured is BEDMAP2 bathymetry, with contours shown at 100, 500, and 1000 metres. Ice shelves are shown in grey, with underlying bathymetry contours shown. Also provided in red are key locations, where EB = Eltanin Bay, RE = Ronne Entrance, AI = Alexander Island, MB = Marguerite Bay and P = Palmer LTER grid point 400.1, used for validation. Ice shelves on the west Antarctic Peninsula are shown with black arrows, where A = Abbot, V = Venable, S = Stange, B = Bach, W = Wilkins and G = George VI. Sections through Belgica Trough leading to Ronne Entrance (S1) and Marguerite Trough (S2) are also shown (black). Inset shows the Bellingshausen Sea and model domain (blue) in relation to the Southern Ocean and Antarctic Ice Sheet.

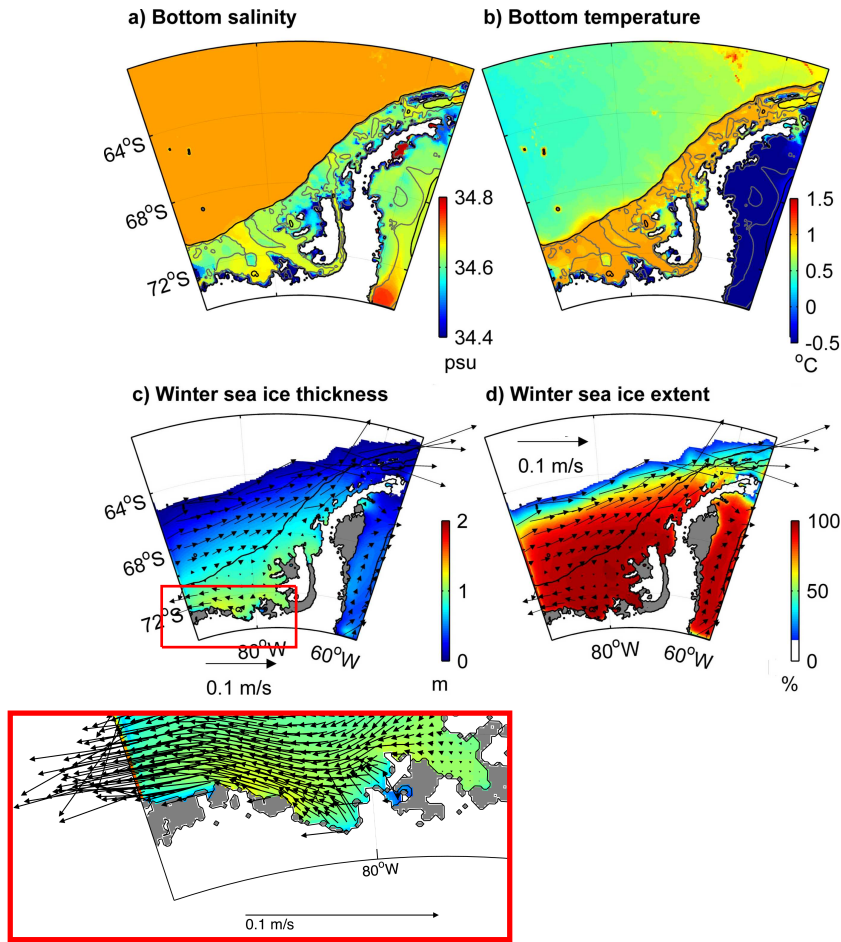

Figure 2: Annual mean a) salinity and b) potential temperature at the seabed for the period 1989-2014. Bathymetry contours shown in grey at 100, 500, and 1000 metres, with the 1000 metre isobath shown in black. Mean winter (JAS) sea ice thickness (c) and extent (d) is shown over the same period masked where sea ice concentration is below 15%, with ice shelves in grey. Vectors of ice velocity at 12 grid point intervals are also shown. Inset highlights the effect of the coastal current on the mean winter sea ice velocities.

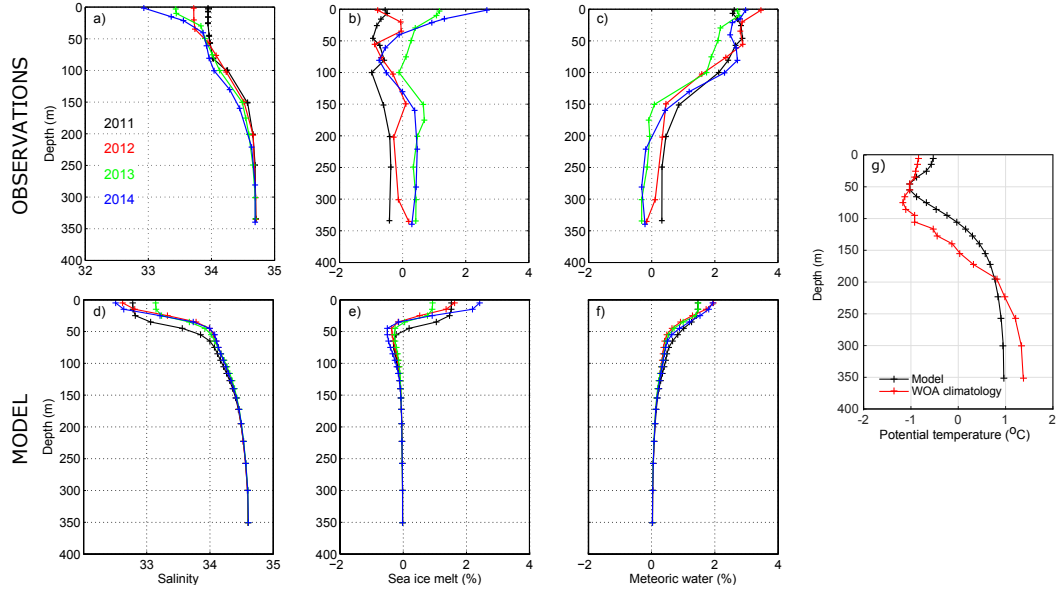

Figure 3: Salinity (a,d), sea ice melt (b,e) and meteoric water content (c,f) at 65°52.6' S, 68°17.0' W (see Figure 1). Top row (a-c) reproduced from Meredith et al. (2016) for validation purposes, with bottom row (d-f) showing the model equivalent for January 2011 (black), 2012 (red), 2013 (green) and 2014 (blue). Climatological potential temperature at the same location (g) is shown for the model (black, averaged over 1989-2014, after the spin-up period) and World Ocean Atlas data (red).

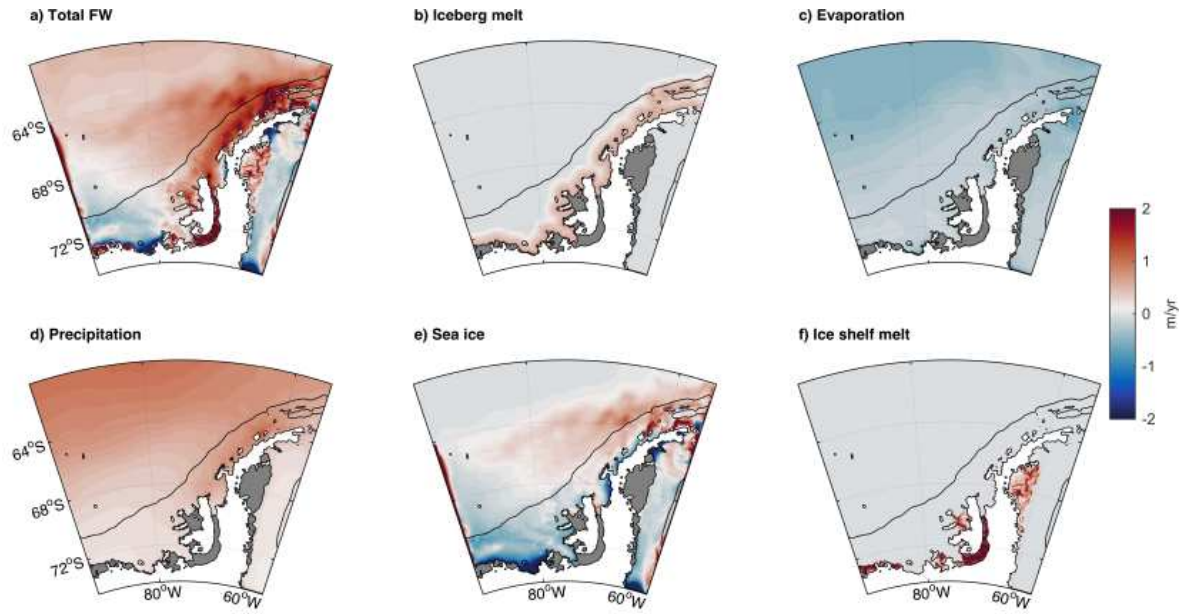

Figure 4: Climatology of freshwater fluxes at injection depth (positive downwards) for a) total freshwater, b) iceberg melt, c) evaporation, d) precipitation, e) sea ice and f) ice shelf melt, all shown on the same scale. Grey regions indicate ice shelves, with the shelf break contoured at 1000 metres.

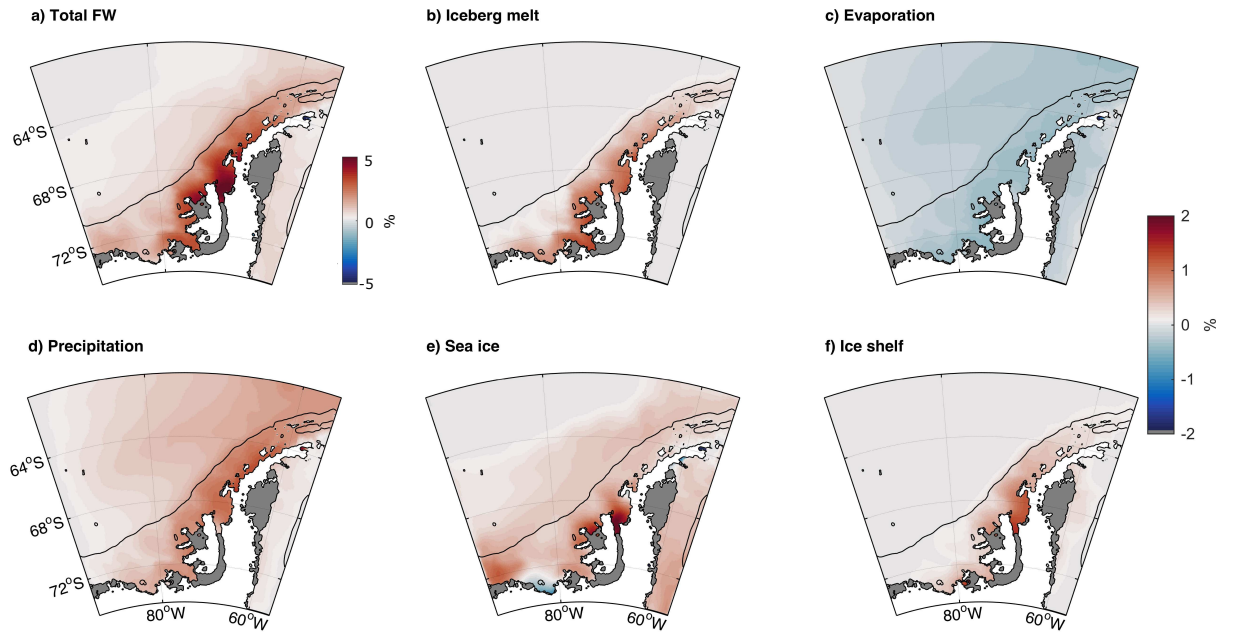

Figure 5: Climatological surface concentration of tracers from 1989-2014 for a) total fresh-water, b) iceberg melt, c) evaporation, d) precipitation, e) sea ice and f) ice shelf melt. Grey regions indicate ice shelves, with the shelf break contoured at 1000 metres. Note the different colour scale for total freshwater.

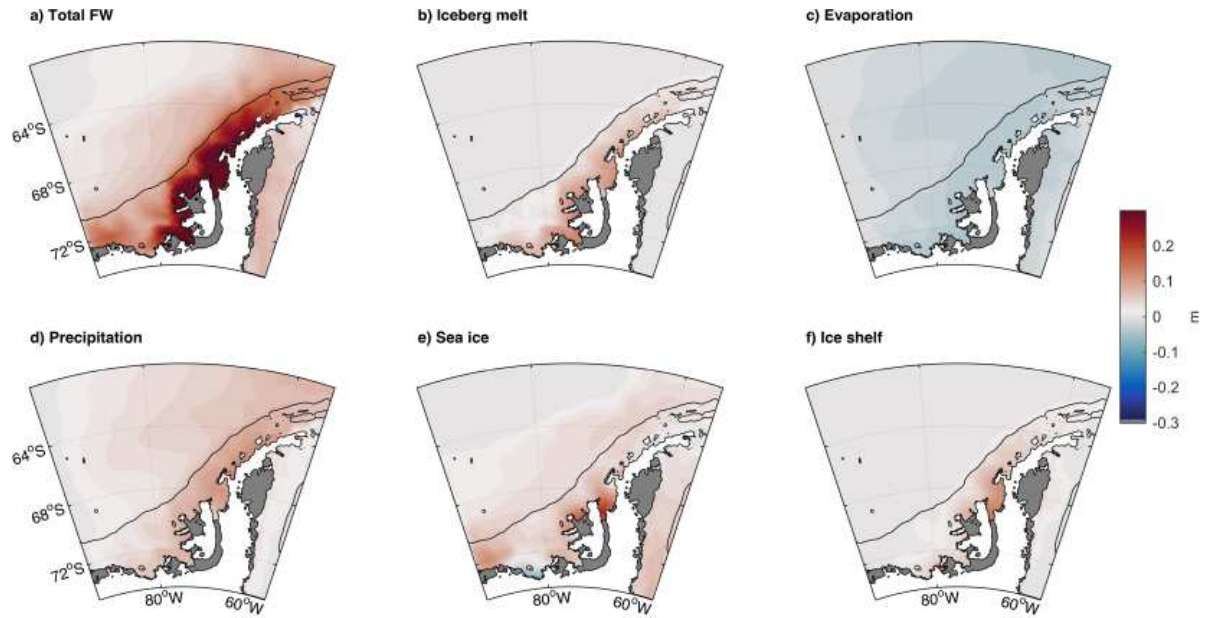

Figure 6: Climatological water-column integral of each tracer from 1989-2014, in metres. a) Total freshwater b) iceberg melt, c) evaporation, d) precipitation, e) sea ice and f) ice shelf melt all shown on the same scale. Bathymetry contours are shown at 100, 500, and 1000 metres.

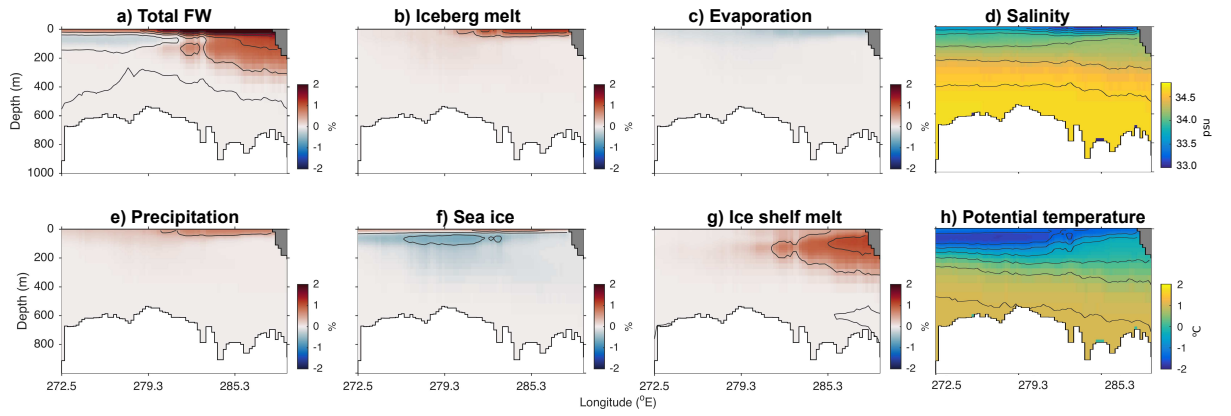

Figure 7: Vertical sections from the shelf break, through the deepest part of Belgica Trough from north-west to south-east through Ronne Entrance (S1 in Figure 1) for the climatology of a) total freshwater content, b) iceberg melt, c) evaporation, d) salinity, e) precipitation, f) sea ice, g) ice shelf melt, and h) potential temperature. Contours are shown at 0.5‰ intervals.

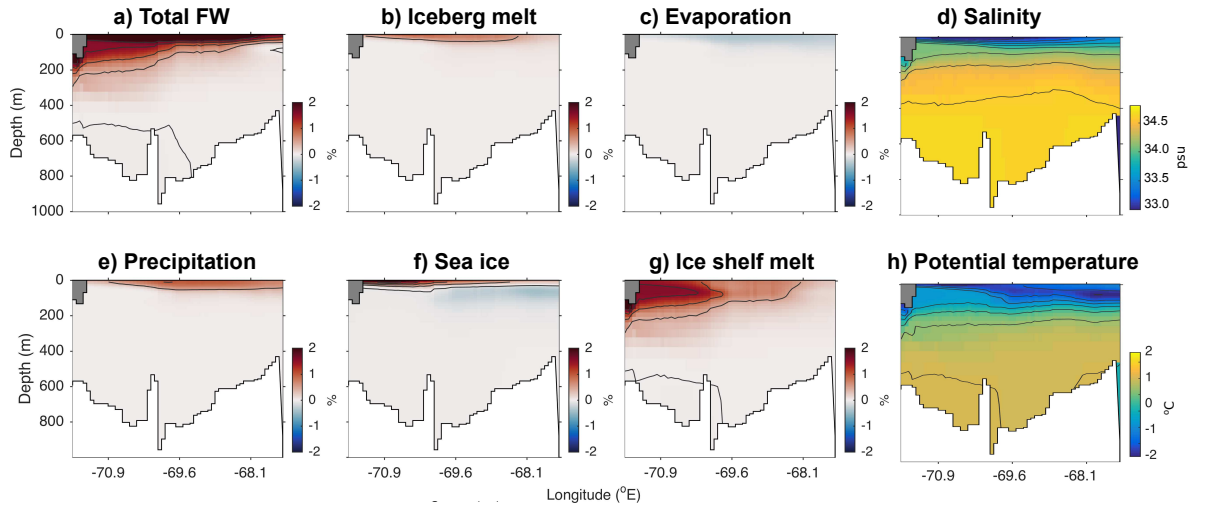

Figure 8: Vertical sections from George VI Ice Shelf through the deepest part of Marguerite Trough to the shelf break (S2 in Figure 1) for the climatology of a) total freshwater content, b) iceberg melt, c) evaporation, d) salinity, e) precipitation, f) sea ice, g) ice shelf melt, and h) potential temperature. Contours are shown at 0.5% intervals.

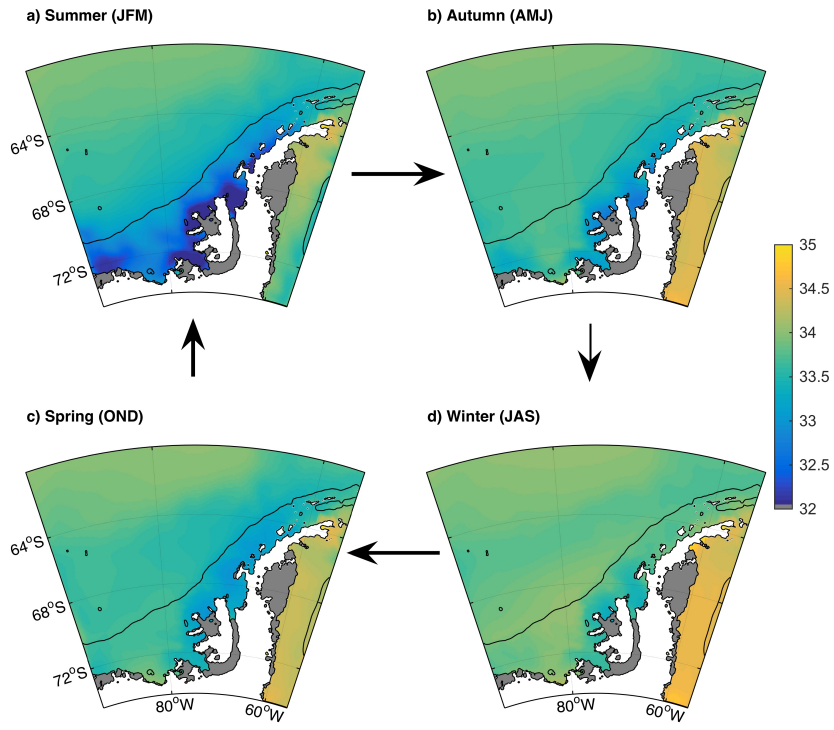

Figure 9: Average seasonal surface salinity, clockwise from top left: a) summer, b) autumn, d) winter and c) spring. Grey regions indicate ice shelves, with the shelf break contoured at 1000 metres.

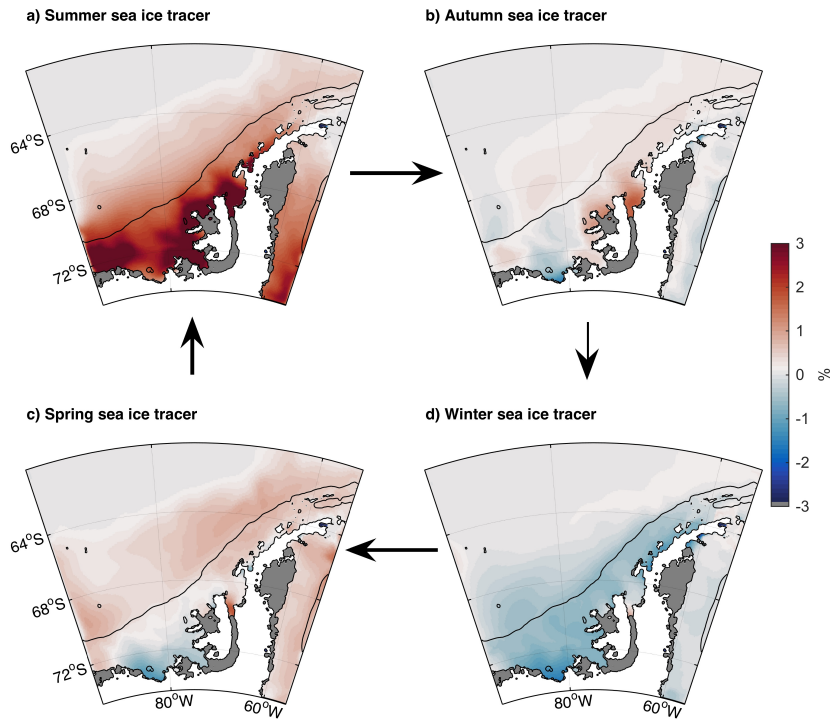

Figure 10: Seasonal distribution of sea ice tracer at the surface. Seasons are shown clockwise from top left: a) summer, b) autumn, d) winter and c) spring. Grey regions indicate ice shelves, with the shelf break contoured at 1000 metres.

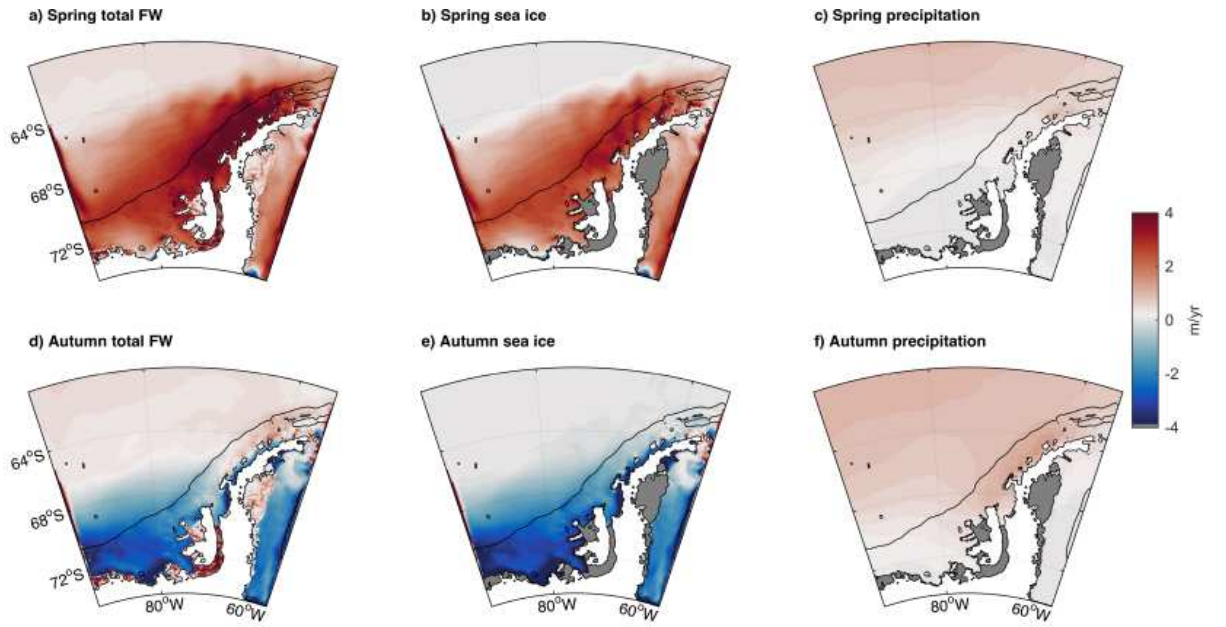

Figure 11: Seasonal distribution of fluxes of (a,d) total freshwater, (b,e) net sea ice melt/growth, and (c,f) precipitation for the spring (top) and autumn (bottom). Grey regions indicate ice shelves, with the shelf break contoured at 1000 metres.

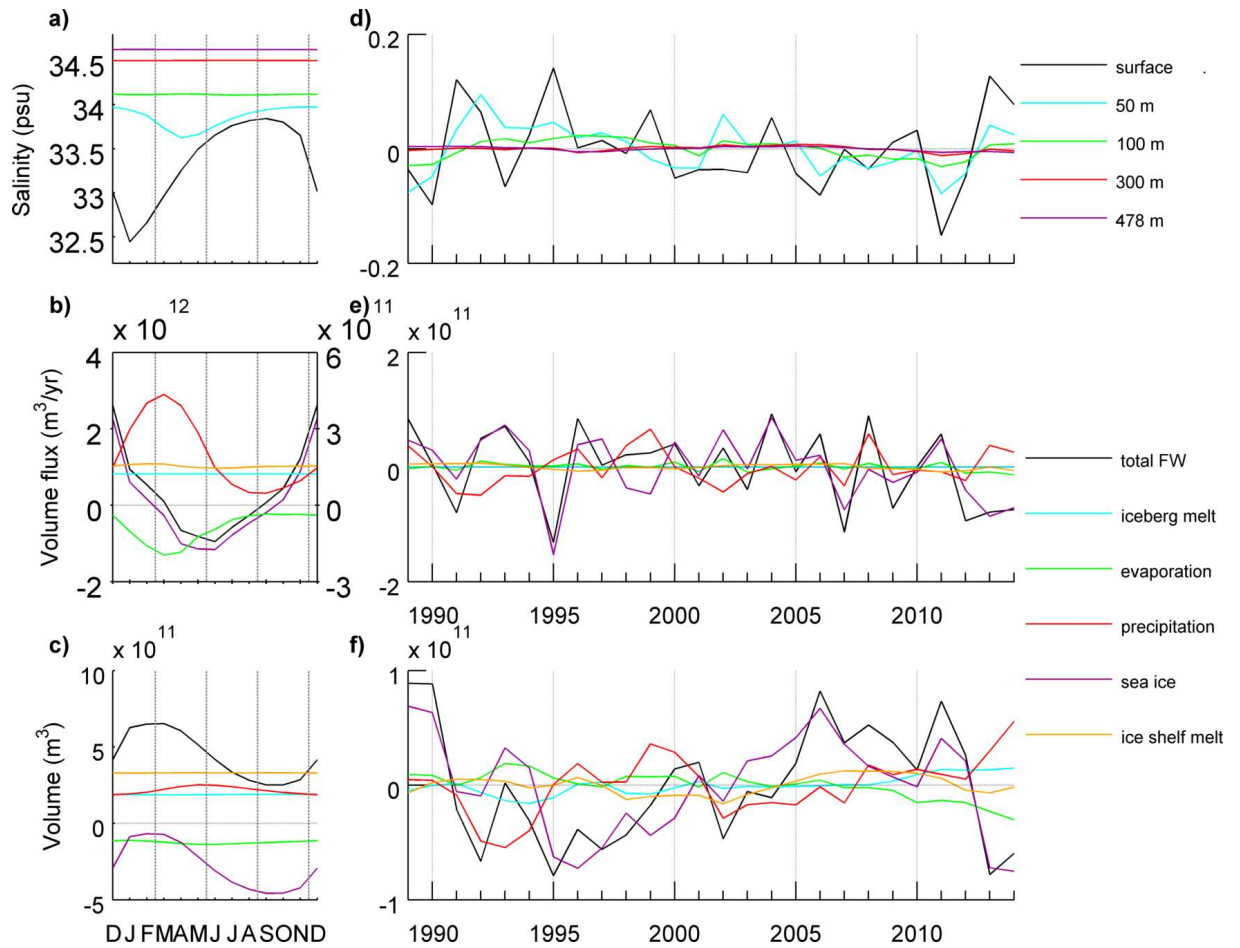

Figure 12: Temporal variation of freshwater on the BS shelf (shallower than 1000 metres). Plots on the left show (from top) seasonal cycles of a) mean salinity at different depths; b) area-integrated freshwater fluxes; and c) volume-integrated tracer content. Plots d)-f) on the right show the timeseries of deviations from the mean seasonal cycle, plotted as annual averages. Note the second y-axis in panel b) for iceberg melt, evaporation, precipitation and ice shelf melt.

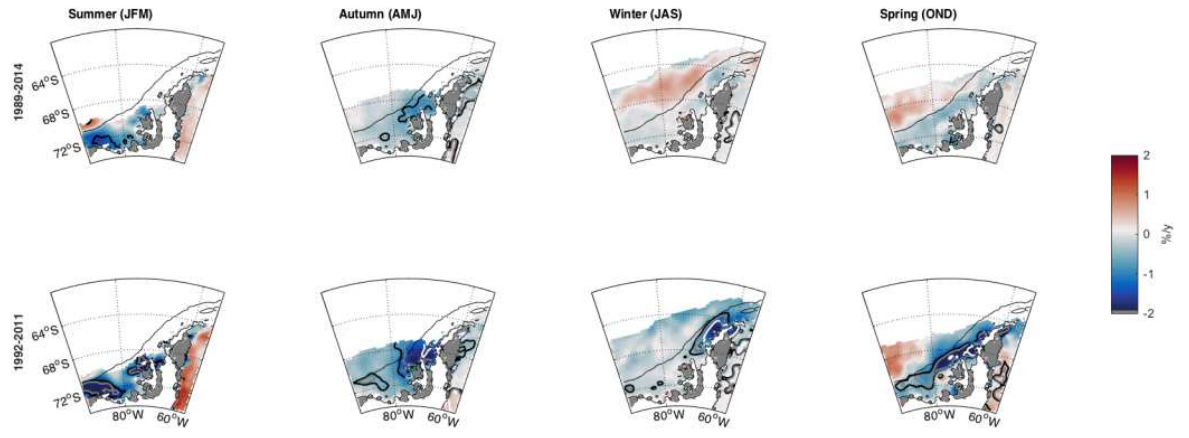

Figure 13: Trends of observed satellite-derived sea ice concentration from Cavalieri et al. (1996) for the full modelled period 1989-2014 (top) and period of increased sea ice flux, 1992-2011 (bottom). Confidence contours are shown at the 90% (black), 95% (grey) and 99% (white) levels. The shelf break is shown in black and ice shelves are in grey.

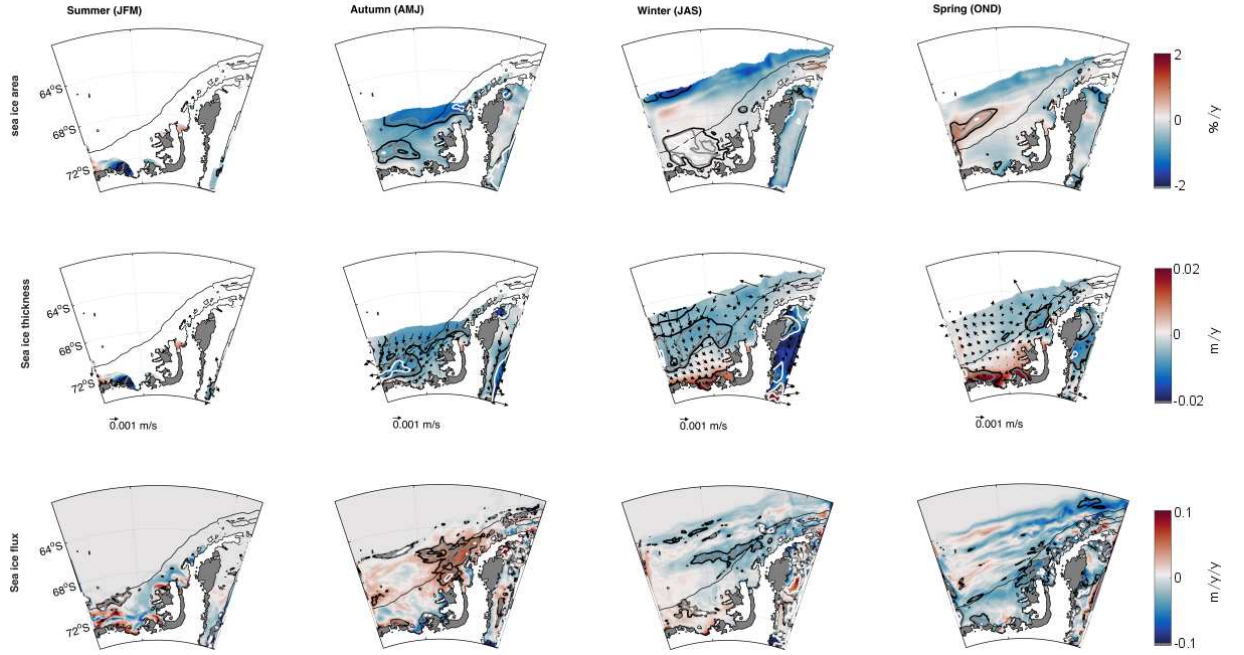

Figure 14: Modelled trends in sea ice area (top), thickness and drift (middle), and sea ice freshwater flux (bottom, positive downward) from 1992-2011. Confidence interval contours are shown at the 90% (black), 95% (grey) and 99% (white) levels. The shelf break is shown in black and ice shelves are in grey.

882 **List of Tables**

883	1	Average ice shelf melt rates (m/yr) from the model are shown	
884		for the period 1989-2014, with error bars indicating 1 standard	
885		deviation of interannual variability. Also shown are the 2003-	
886		2008 average ice shelf melt rates from Rignot et al. (2013) and	
887		1979-2010 melt rates from Depoorter et al. (2013) where avail-	
888		able, with error bars showing observational error. Equivalent	
889		freshwater input in Gt/yr is also shown in brackets.	54
890	2	Table showing the annual mean, seasonal variability, interan-	
891		annual variability, and correlation against the total interannual	
892		timeseries for each flux ($\times 10^{11}$ m ³ /y) and tracer ($\times 10^{11}$ m ³)	
893		on the shelf from Figure 12. The annual cycle was calculated	
894		by taking the average of each month over the 26 years, which	
895		was then averaged to produce the annual mean. Anomalies	
896		were calculated by removing the annual cycle from the time-	
897		series, taking the yearly average and calculating the standard	
898		deviation of the result. Significance of correlation is indicated	
899		at the 90% (italic), 95% (bold) and 99% (bold, italic) levels. .	55
900	3	Interannual trends in annual-mean anomaly from mean sea-	
901		sonal cycle shown for on-shelf salinity at various levels (y^{-1}),	
902		and in the total shelf tracer content (km^3y^{-1}). Trends are	
903		shown for the full time period and 1992-2011, identified as	
904		a period of freshening. Significance at the 90% (italic), 95%	
905		(bold) and 99% (bold, italic) confidence levels are indicated. .	56

Table 1: Average ice shelf melt rates (m/yr) from the model are shown for the period 1989-2014, with error bars indicating 1 standard deviation of interannual variability. Also shown are the 2003-2008 average ice shelf melt rates from Rignot et al. (2013) and 1979-2010 melt rates from Depoorter et al. (2013) where available, with error bars showing observational error. Equivalent freshwater input in Gt/yr is also shown in brackets.

	Model (1989-2014)	Rignot <i>et. al.</i> , 2013 (2003-2008)	Depoorter <i>et. al.</i> , 2013 (1979-2010)
George VI	4.74±0.19 (105.50±4.10)	3.8±0.7 (89±17)	2.88±0.83 (144±42)
Wilkins	1.00±0.28 (13.07±3.80)	1.5±1 (18.4±17)	- -
Bach	0.43±0.03 (1.26±0.09)	2.3±0.3 (10.4±1)	- -
Stange	1.11±0.26 (9.08±2.20)	3.5±0.7 (28.0±6)	- -
Venable	1.99±0.34 (5.02±0.9)	6.1±0.7 (19.4±2)	4.82±0.83 (15±3)
Abbot	2.26±0.19 (20.13±1.8)	1.7±0.6 (51.8±19)	2.72±0.70 (86±22)

Table 2: Table showing the annual mean, seasonal variability, interannual variability, and correlation against the total interannual timeseries for each flux ($\times 10^{11} \text{ m}^3/\text{y}$) and tracer ($\times 10^{11} \text{ m}^3$) on the shelf from Figure 12. The annual cycle was calculated by taking the average of each month over the 26 years, which was then averaged to produce the annual mean. Anomalies were calculated by removing the annual cycle from the timeseries, taking the yearly average and calculating the standard deviation of the result. Significance of correlation is indicated at the 90% (italic), 95% (bold) and 99% (bold, italic) levels.

	Annual mean	Seasonal variability (1 sd)	Interannual variability (1 sd)	Correlation
Total flux	2.11	10.26	0.67	<i>N/A</i>
Sea ice flux	-0.79	9.95	0.57	<i>0.82</i>
Precipitation flux	2.04	1.49	0.31	0.27
Evaporation flux	-0.92	0.61	0.07	0.61
Iceberg flux	1.23	<i>N/A^o</i>	<i>N/A^o</i>	<i>N/A^o</i>
Ice shelf flux	1.53	0.06	0.05	0.09
Total tracer	4.41	1.62	0.51	<i>N/A</i>
Sea ice tracer	-2.77	1.57	0.44	<i>0.84</i>
Precipitation tracer	2.19	0.23	0.25	0.04
Evaporation tracer	-1.25	0.09	0.12	0.09
Iceberg tracer	1.89	0.01	0.08	0.13
Ice shelf tracer	3.30	0.01	0.08	0.36

^oNot applicable as prescribed iceberg flux is temporally uniform

Table 3: Interannual trends in annual-mean anomaly from mean seasonal cycle shown for on-shelf salinity at various levels (y^{-1}), and in the total shelf tracer content (km^3y^{-1}). Trends are shown for the full time period and 1992-2011, identified as a period of freshening. Significance at the 90% (italic), 95% (bold) and 99% (bold, italic) confidence levels are indicated.

	1989-2014	1992-2011
Salinity (surface)	-0.0011	-0.0047
